1 Introduction

This vignette describes how you can use the OhdsiRTools package to perform logging. Logging is the activity of recording events that occur during an analysis in a log. The log can be used for example for for debugging, profiling (understanding performance bottlenecks), and audits.

1.1 Terminology

- Logger: An object that can receive events, and writes them to a log. A logger has a name, a prespecified event level (only events at or above that level are logged), and one or more appenders.
- Event: Consists of a message and an event level.
- Event level: Each event has an associated level. These levels (in ranked order) are
 - TRACE: Events to mark the analysis has passed through some code.
 - DEBUG: Events to help understand the state of the code (e.g. whether a variable has a value).
 - INFO: Events typically displayed to the user to inform of the progress.
 - WARN: Events that indicate something probably requires attention.
 - ERROR: Events indicating something went wrong.
 - FATAL: Events indicating something went wrong, causing the analysis to terminate.
- **Appender**: An object that writes to a destination, for example the console or a file. An appender uses a **layout** to format its messages. There currently are two types appenders:
 - Console appender: Writes to the console, created using the createConsoleAppender function.
 - File appender: Writes to a file, created using the createFileAppender function.
- Layout: Objects specifying the format in which the log will be created. The following layouts are available:
 - layoutSimple: Only outputs the message.
 - layoutTimestamp: Adds the current time and date to the message.
 - layoutStackTrace: Adds the time and date, and full stack trace to the message.

- layoutParallel: Includes the thread identifier, name of the package and function raising the event, the current time and date, the message level, and the message itself.

2 Creating a console logger

The code below demonstrates how one would create a logger that writes all events at level INFO or greater to the console using a layout with time stamp:

Note that the message is displayed twice. This is because there is a default logger that uses the simple layout and threshold = "INFO", and writes to console. We can remove this logger before registering our logger to avoid duplication:

2.1 Shorthand

A shorthand for creating a simple console logger is offered by the addDefaultConsoleLogger function. The code

```
addDefaultConsoleLogger()
```

3 Creating a file logger

Probably more useful is a file logger. In the code below, we instantiate a logger that writes to file, using a threshold of TRACE (so including all events), and using the layout for parallel processing.

```
logFileName <- "log.txt"</pre>
logger <- createLogger(name = "PARALLEL",</pre>
                        threshold = "TRACE",
                        appenders = list(createFileAppender(layout = layoutParallel,
                                                              fileName = logFileName)))
registerLogger(logger)
logTrace("Executed this line")
logDebug("There are ", length(getLoggers()), " loggers")
logInfo("Hello world")
#> 2018-06-06 07:03:03 Hello world
We can read the log file:
writeLines(readChar(logFileName, file.info(logFileName)$size))
#> 2018-06-06 07:03:03
                         [Main thread]
                                          TRACE
                                                  evaluate
                                                               timing_fn
                                                                           Executed this line
#> 2018-06-06 07:03:03
                         [Main thread]
                                          DEBUG
                                                  evaluate
                                                               timing_fn
                                                                           There are 2 loggers
#> 2018-06-06 07:03:03
                         [Main thread]
                                          INFO
                                                  evaluate
                                                               timing_fn
                                                                           Hello world
And clean it up when we're done:
unlink(logFileName)
```

3.1 Shorthand

A shorthand for creating the file logger detailed here is offered by the addDefaultFileLogger function. The code

4 Warnings and fatal errors

All R warnings and errors are automatically logged, and therefore do not require explicit logging. For example:

```
clearLoggers()
addDefaultFileLogger(logFileName)
warning("Danger!")
```

```
as.numeric('a')
# This throws an error:
a <- b
writeLines(readChar(logFileName, file.info(logFileName)$size))
#> 2018-06-06 07:03:03
                         [Main thread]
                                         WARN
                                                 evaluate
                                                              timing_fn
                                                                          Danger!
#> 2018-06-06 07:03:03
                        [Main thread]
                                         WARN
                                                              timing_fn
                                                                          Warning: NAs introduced by coer
                                                 evaluate
#> 2018-06-06 07:03:03
                        [Main thread]
                                         FATAL
                                                 evaluate
                                                              timing_fn
                                                                          Error: object a not found
```

5 Logging when parallel processing

This throws a warning:

The logging functions are designed to work with the parallel processing functions included in this package. The layoutParallel records thread identifiers, making it possible to later untangle the various threads. Below is a simple example:

```
unlink(logFileName) # Clean up log file from the previous example
clearLoggers() # Clean up the loggers from the previous example
addDefaultFileLogger(logFileName)

cluster <- makeCluster(3)

fun <- function(x) {
    OhdsiRTools::logInfo("The value of x is ", x)
    # Do something
    if (x == 6)
        OhdsiRTools::logDebug("X equals 6")
        return(NULL)
}

dummy <- clusterApply(cluster, 1:10, fun, progressBar = FALSE)

stopCluster(cluster)

writeLines(readChar(logFileName, file.info(logFileName)$size))</pre>
```

```
[Main thread]
#> 2018-06-06 07:03:03
                                        TRACE
                                                 evaluate
                                                             timing_fn
                                                                          Initiating cluster with 3 thread
#> 2018-06-06 07:03:04
                        [Thread 1]
                                    TRACE
                                                     Thread 1 initiated
                                                     Thread 2 initiated
#> 2018-06-06 07:03:04
                        [Thread 2]

6 Shiny log viewer

A Shiny app for viewing a log file created using the layoutParallel is included in the package. To explore the log created in the prior example, run

```
launchLogViewer(logFileName)
```

to launch the viewer shown in Figure 1.
